Abstract

Photovoltaic/thermal (PV/T) collectors combine features of a solar thermal collector and a PV module into a single panel to maximize the collection of thermal and electrical energy. There currently are several simulation models in TRNSYS for PV/T modules, however, these are for PV/T panels cooled by circulating a fluid through an integral “tube and sheet” absorber (i.e., heat exchanger) and are not suitable for a large group of commercially available PV/T panels that incorporate a “fully wetted” absorber bonded to the back side of a conventional PV panel. The existing PV/T models in TRNSYS are also not suitable for simulating the performance of a panel when the surround ambient temperature is higher than the inlet fluid temperature, and as such, a new PV/T model was developed and implemented. This model iteratively solves for the panel's outlet fluid temperature and estimates the PV power output under specified conditions. This paper describes the theoretical basis of the new model and compares the simulated and experimental data. To test the new model, simulation results were compared to data experimentally measured on an operating PV/T panel. These results indicate that the new TRNSYS model was able to predict the performance of the PV/T panel to within the estimated measurement error.

Introduction

Several different numerical models for PV/T panels have been developed since this concept first emerged. Florschuetz (1979) developed an extension to the Hottel-Whillier model of flat plat thermal collectors to predict the performance of a sheet-and-tube PV/T panel. The model used a modified collector heat removal factor ($F_R$), modified collector efficiency factor ($F_T$), modified overall collector heat loss coefficient ($\overline{U}_L$), and modified solar radiation ($\overline{S}$) to calculate the production of electrical and thermal energy. Eq.'s 1 and 2, below, were used to calculate the energy production of the PV/T panel (Florschuetz, 1979).

$$Q_e = \frac{A S n_{\text{th,amb}}}{\alpha} \left[ 1 - \frac{n_{\text{th,amb}} \beta}{n_{\text{th,amb}}} \right] \left[ \frac{\overline{F}_R(\overline{T}_i - \overline{T}_{\text{amb}})}{\overline{U}_L(1 - \overline{F}_R)} \right] \left( \overline{S} - \overline{U}_L(\overline{T}_i - \overline{T}_{\text{amb}}) \right)$$

Tiwari and Sodha (2006) created a theoretical model and compared the simulated value of daily thermal efficiency of the PV/T panel to the experimental results found by Huang et al., (2001). A cross-sectional view of the PV/T panel used by Huang et al., (2001) and simulated by Tiwari and Sodha (2006) is shown in Figure 1.

The model was very similar to the Hottel-Whillier-Bliss equation of thermal efficiency but included two additional penalty factors; due to the solar cell material, tedarlar, the two layers of ethylene vinyl acetate (EVA) that encapsulate the PV cells and glass cover ($h_{P2}$) and due to the interface between the tedarlar and the working fluid ($h_{P2}$) (Eq. 3).

$$\eta_{th} = \frac{F_R}{h_{P1} h_{P2} (\tau \alpha) - U_L \frac{T_i - T_{\text{amb}}}{T_T}}$$

The study predicted a daily efficiency of approximately 58% which showed good agreement of with results obtained by Huang et al., (2001) under similar operating conditions (Tiwari and Sodha, 2006).

A review of the current PV/T models in TRNSYS was also performed as part of the International Energy Agency’s Solar Heating and Cooling Programme Task 35 “PV/Thermal Solar Systems”. The review looked three TRNSYS component models (Type 50, 555 and Type 56(0, 3, 6, 7, 8, 9)) as well as other TRNSYS models that had been independently developed. It was noted that the Type 50 model had eight operational modes but contained several errors that limited its usability. Type 555 was specifically designed for an unglazed air collector and Type 56(0, 3, 6, 7, 8, 9) was only applicable for systems where the collector was integrated into the building.
As a result of these limitations, a number of new generic TRNSYS components were developed, including:

- Type 201 for transpired PV/T air collectors,
- Type 250 for modelling of glazed and unglazed flat plat PV/T collectors using any fluid, and,
- Type 251 for concentrating PV/T collectors.

Figure 2: Flow chart demonstrating the process of Type 348 (Jaczko, 2017).
Type 250 is applicable for simulating fully wetted PV/T panels, however the model does not account for heat transfer from the ambient surroundings to the collector in cases when the collector surface temperature is lower than the surrounding air temperature (Collins, 2009) such as the case of a PV/T panel cooled by a heat pump to temperatures below the surrounding ambient temperature.

In the present study, the model for a fully wetted flat plate thermal collector was modified to include the collection of electrical energy and to allow operation at panel temperatures below the ambient air temperature (even with zero solar irradiance). To investigate the accuracy of the new model, the performance of a commercially available PV/T collector was measured over a range of operating conditions and compared to the new model’s predicted performance under similar conditions. The new model was designated Type 348.

Modeling Approach

A PV/T model, Type 348, was created based on a previously developed model of a flat-plate thermal collector (Harrison 2017). The simulation starts by guessing the initial outlet fluid temperature, average absorber plate temperature and PV cell temperature. Using these values, the one-dimensional heat transfer between the collector fluid, the absorber plate, the PV cells, the glass cover and the surroundings is calculated. Type 348 then recalculates the temperatures that were guessed at the start and iteratively finds the performance of the PV/T collector. If multiple panels are connected in series the inlet temperature of the next panel is set to the outlet temperature of the previous panel and the total thermal and electrical power outputs are found for each time step of the main system simulation. Figure 2 illustrates the process of determining the performance of the panel in the TRNSYS subroutine.

Type 348 relies on linear factors relating the efficiency of the PV cells to the cell temperature and it is assumed that the PV module is always operating at its maximum power-point. The thermal portion of the model was based on a back of the collector and the surface temperature of the absorber plate temperature and ambient temperature.

As previously mentioned, the efficiency of the PV module depends on the temperature of the cells ($T_{PV}$) and the packing factor ($PF$) of the cells on the panel (Eq. 6),

$$
\eta_{PV, e} = \eta_{PV, ref} \cdot PF \left( 1 - \beta \left( T_{PV} - T_{ref} \right) \right)
$$

where $\beta$ represents the temperature coefficient of the photovoltaic cells and $T_{ref}$ is the reference temperature for the PV cells at the reference efficiency ($\eta_{PV, ref}$). The electrical power generated by the PV/T panel is calculated using Eq. 7.

$$
\dot{Q}_{elec} = G \cdot (\alpha T) \cdot A_p \cdot \eta_{PV, e}
$$

The temperature of the glass cover is determined by iteratively solving the following equation,

$$
\left( \frac{T_{cover, ave} - T_{plate, ave}}{R_{plate-to-cover}} \right) = h_w \left( T_{cover, ave} - T_{amb} \right) + \ldots
$$

where $h_w$ represents the convection heat transfer coefficient due to wind $W/\text{m}^2$, $E_{cover}$ represents the emissivity of the glass cover, $\sigma$ is the Stephan-Boltzmann constant i.e., $5.67 \times 10^{-8} \text{ W}/(\text{m}^2 \cdot \text{K}^4)$. The thermal resistance between the absorber plate and the outer surface of the cover accounting for the EVA that encapsulate the PV cells and the resistance of the glass, is given by,

$$
R_{plate-to-cover} = R_{EVA} + R_{cover} = \frac{l_{EVA}}{k_{EVA}} + \frac{l_{cover}}{k_{cover}}
$$

The convection coefficient across the top of the collector was calculated using the correlation from McAdams (1954),

$$
h_w = 5.7 + 3.8V_w
$$

where $V_w$ represent the wind speed in m/s (McAdams, 1954). As seen in Eq. 11, the fluid temperature at outlet of the collector, as well as the plate and PV average temperatures, are initially estimated and then recalculated using the value of the absorbed useful thermal energy, and the mean fluid temperature is then estimated by Eq. 12.

$$
T_{fluid, outlet} = T_{fluid, inlet} + \frac{Q_u}{m \cdot c_p}
$$

\[
T_{\text{fluid, ave}} = \frac{T_{\text{fluid, inlet}} + T_{\text{fluid, outlet}}}{2} \tag{12}
\]

To estimate the average plate temperature, the Nusselt number for parallel plates and convection heat transfer coefficient were determined from,

\[
Nu = 4.9 + 0.0606 \left( \frac{Re \cdot Pr \cdot D_h}{L} \right)^{\frac{11}{10}} \tag{13}
\]

\[
h_{\text{fluid}} = Nu \cdot \frac{k_{\text{fluid}}}{D_h} \tag{14}
\]

where \(Re\) and \(Pr\) are the Reynolds and Prandtl numbers, \(D_h\) represents the hydraulic diameter of the collector in m, \(L\) represents the length of the collector absorber channel in m and \(k_{\text{fluid}}\) represents the conductivity of the collector fluid W/(m·K) (Duffie and Beckman, 2013). Thus, the average absorber plate temperature is found by,

\[
T_{\text{plate, ave}} = T_{\text{fluid, ave}} - \frac{\dot{Q}}{h_{\text{fluid}} \cdot P_{\text{channel}} \cdot L} \tag{15}
\]

where \(P_{\text{channel}}\) represented the perimeter of the collector fluid channel in m. Finally, the temperature of the PV module was found using Eq. 16.

\[
T_{PV} = T_{\text{fluid, ave}} + \frac{R_{\text{EVA}} \left( T_{\text{plate, ave}} - T_{\text{cover, ave}} \right)}{R_{\text{plate-to-cover}}} \tag{16}
\]

The average temperatures of the glass cover, the absorber plate, the collector and the PV module are all converted into absolute temperatures (i.e., degrees Kelvin) in the subroutine and are solved for iteratively.

Table 1 contains the TRNSYS model parameters, inputs and outputs for Type 348 and evaluates if equivanent parameters are used by Type 250. The inputs and outputs are very similar to those for Type 250, however Type 348 includes the emissivity and reflectivity of ground while Type 250 assumes the temperature behind the panel is equal to the ambient temperature. Type 348 allows for iterations based on the number of panels connected in series as seen in Figure 2. Type 250 includes the collector efficiency factor as a parameter to calculate the thermal performance of the panel while Type 348 uses the dimensions of the flow channel and Eq.’s 13 and 14. The same PV module parameters are used in both models and both account for heat loss from the back of the panel. Type 250 does not account for interactions between the PV cells and the bonded glass layer and EVA layers and thus does not include the relevant parameters.
**Experimental Methodology**

For this study, a commercially available, fully-wetted absorber plate design (manufactured by DualSun) was modelled. Two versions of the product are available, consisting of: conventional PV panels with plate heat exchangers bonded to the back of the panel to extract heat – the plate heat exchangers were not insulated from the ambient (Figure 3) and, conventional PV panels with plate heat exchangers bonded to the back of the panel to extract heat – the plate heat exchangers were insulated from the ambient in a manner similar that described by Zondag, et al. 2003 (DualSun, 2017).

The PV/T model was compared to experimental data of DualSun Wave PV/T collector without back insulation. The test apparatus used for this study consisted two parts; a thermal loop and an electrical loop. Local mains water was run through two DualSun Wave PV/T (Figure 4) collectors connected in series and the temperature at the inlet and outlet of the collector rig and the flow rate of the mains water were recorded. The PV panels of each collector were also connected in series and to a resistor bank that was set to the estimated maximum power point of the collectors. The voltage and amperage output of the PV/T panels was monitored. Two inclined pyranometers were used to measure the total and diffuse radiation incident on the PV/T array. The ambient temperature was monitored using a shaded and shielded thermocouple and the local wind speed in front of the panels was monitored using a weather station. All measurements, except for wind speed, were monitored every four seconds. Due to limitations of the weather station the wind speed was only recorded every twelve minutes. The PV/T array’s performance was tested using the operating conditions in Table 2.

**Results**

To determine the accuracy of the new TRNSYS PV/T model, Type 348, a series of tests were performed on two commercially available fully wetted liquid PV/T panels as shown in Figure 4. Table 2 details the operation conditions under which the tests were performed. The total rate of collection is designated as “Q_total”, the rate of thermal energy collection is designated as “Q” and the rate of electrical energy collection is designated as “Q_{PV}” in Figures 6 and 10.

Figure 5 displays the rate at which thermal energy was collected during the test period on July 29th, 2017. The average percentage difference between the experimental and simulated collection rate was 2.60% or 35.4 W. The outdoor air temperature was above the inlet temperature of the collector fluid for the duration of the experiment.

Figure 6 shows the plot of the thermal and electrical energy collection rate predicted by Type 358 and the collection rates calculated from the experimental data for July 31st, 2017. The collector fluid was below the ambient temperature for the entire test. The average difference in the rate of thermal and electrical collection was 7.5% and 8.4%, which is within estimations of the error of the experimental data. It was also observed that Type 348 reacted more rapidly to changes in the

outdoor conditions. This is due to the model assuming that the PV/T panels do not have thermal capacity.

Figure 7 shows the outlet temperature of the PV/T panels for August 21st, 2017 obtained experimentally and from Type 348. The temperature of the collector fluid was above the ambient temperature for the duration of the test. Average difference of the predicted and experimental outlet temperatures was 0.91°C or a 2% difference. It is observed that the lack of thermal capacitance in the model results in a quicker reaction to changes in the conditions. The difference in the rate of thermal energy collection for August 21st, 2017 was 146.7 W and Figure 8 show the models rapid reaction to changes in operating conditions.

Figures 9 and 10 show the results of the August 23rd test. The ambient air temperature was below the inlet fluid temperature for the duration of the test and the PV cells were connected. The average fraction of diffuse radiation was 0.442 and ranged during the testing period between 0.198 and 0.931. Figure 9 show the recorded and simulated collector fluid outlet temperatures. The average difference between the model and the
experimental outlet temperature was 1.47°C. Figure 10 shows the total rate of thermal and electrical energy collection on August 23rd. The average difference between the experimental and predicted output was 172.5 W. This is within the experimental error for the apparatus.

**Analysis**

The experimental and simulation performance of the PV/T panels had very good agreement when the collector fluid inlet temperature was lower than the ambient air as seen in Figures 5 and 6. Figure 8 illustrates the impact of this lack of capacitance as the experimental thermal energy collected is very small and relatively constant for the entire test while the rate of the thermal energy collector predicted by Type 348 does vary with changes in outdoor conditions. Both the thermal and electrical performance were well within the range for the duration of the test. It was also observed that Type 348 reacted more rapidly to changes in the outdoor conditions as was seen in Figures 8 and 10 during fluctuating test conditions as the model is steady state. This issue was seen when the PV/T panels operate above the ambient temperature. The small difference in the outlet fluid temperature of the experimental and simulated results resulted in a much larger difference in thermal energy collection. This difference was still within the experimental error.

**Conclusion**

A new TRNSYS model of a fully wetted liquid photovoltaic/thermal collector that includes the absorption of ambient energy was developed. The model was used to compare the simulated and experimental performance of commercially available PV/T panels under a range of operating conditions. The model showed very good agreement when tested with inlet temperatures above and below ambient temperature.

As the model is steady-state, the simulated performance tended to react more rapidly to changes in temperature and incident radiation on the panel.
